Abstract

The effects of glucan and liposomized glucan, alone or co-administered with vitamin C, and empty liposomes on hepatic fibrosis in mice infected with *Mesocestoides corti* (*M. vogae*) tetrathyridia were studied. Preparations were administered every third day from day 7 to day 31 post-infection (p.i.), nine doses in total. Activities of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and cholesterol levels were measured in sera collected on days 11, 15, 21, 28, 32, 42, 50 and 65 p.i. Liver fibrosis was studied on the same days by measuring hydroxyproline concentration, which is considered a marker for collagen content. Larvicidal effects of the glucan and liposome preparations were estimated on day 65 p.i. in the liver and peritoneal cavity. Glucan formulations significantly enhanced collagen content, most prominently after administration of liposomized glucan in combination with vitamin C. Activities of both enzymes and cholesterol levels were slightly modified after administration of glucan alone. Liposomized glucan with vitamin C significantly increased ALT and AST activity and cholesterol levels up to days 28–32 p.i., after which they plateaued or declined. The most pronounced decrease was after administration of liposomized glucan and vitamin C. The same pattern of biochemical parameters in serum was observed after administration of empty liposomes, however, collagen content was not modified significantly. Larval counts in the liver and the peritoneal cavity were significantly reduced after treatment with either glucan formulation, but were unaffected following treatment with empty liposomes. In summary, intense fibrosis in the liver of mice treated with liposomized glucan and vitamin C did not result in the most extensive parenchymal cell injury but, rather in the highest efficacy of treatment. Liposomal lipids were probably utilized in the reparation of the damaged parenchymal cells, while glucan stimulated phagocytic cells.

Introduction

Non-specific immunosuppression is a common feature of several helminthic diseases. *Mesocestoides corti* infection has been shown to inhibit progressively the accessory activity of murine macrophages by means of T-cells (Jenkins *et al.*, 1990), activity of which is modified by the antigen produced by larvae to promote their survival (Kadian *et al.*, 1994). *Mesocestoides corti* tetrathyridia proliferate rapidly in the liver and the peritoneal cavity of the hosts and could serve as a suitable model in immunological and pharmacological studies for slowly developing metacestodes of *Echinococcus granulosus* and *E. multilocularis* (WHO, 1984). In the liver, during the reparative phase of infection (days 10–21 p. i.), extensive fibrosis is initiated, followed by the formation of capsules around the parasites (Specht & Widmer, 1972). Hepatic fibrosis is a feature of many chronic liver diseases. It is a dynamic process involving complex interactions between several cell types mediated by various cytokines, including transforming growth factor (TGF)-α, interleukin (IL)-1, tumour necrosis factor (TNF)-α and others (Burt & Oakley, 1993, Tsukamoto, 1999). Most of the growth factors involved are derived from activated Kupffer cells, and there is evidence of a complex interplay between mediators (Burt & Oakley, 1993). Pollacco *et al.* (1978) reported that encapsulation of *M. corti* tetrathyridia by collagenous capsules is a T-cell dependent process that does not occur in hypothyomic mice. On the other hand, the number of larvae recovered from hypothymic mice was considerably higher than from control mice, indicating that the formation of capsules around the larvae restricts multiplication of the larvae in the liver (Pollacco *et al.*, 1978).

β-glucan extracted from cell walls of the fungus *Saccharomyces cerevisiae* is a polysaccharide with a β-1,3-linkage and molecular weight — 1 × 10^6 D (Mizuno *et al.*, 1995). To date, several immunomodulatory activities of β-glucan have been shown. Williams *et al.* (1996), Mayell (2001) and others reported that glucan is able to stimulate the phagocytic activity of macrophages, to activate natural killer cells and T-and B-lymphocytes. Moreover, administration of glucan resulted in an increased production of cytokines IL-1, IL-2, IL-6, TNF-α and interferon (IFN)-γ in macrophages (Rasmussen & Seljelid, 1991; Kidd, 2000) and generation of nitric oxide (Sakurai *et al.*, 1997). Therefore the potential of immunomodulatory compounds, such as glucans is investigated for the therapy of various infections in combination with drugs or alone in many laboratories. However, most of immunomodulators are water-soluble compounds, which represents the drawback in terms of their half-life in the circulation. In this regard their entrapment in a suitable carrier such as liposomes considerably extended their presence in the circulation (Fidler & Kleinerman, 1994).

Liposomes are spherical vesicles formed of one or several phospholipid bilayers which, since their discovery by Bangham *et al.* (1965), have found numerous applications as carriers of both lipophilic and hydrophilic drugs (Gregoridiadis, 1988). *In vivo* liposomes are gradually cleared by the mononuclear phagocytic system (MPS), which could be an advantage when liposomes serve as carriers of adjuvants and antigens (Alving, 1983). Previously we showed that administration of liposome-encapsulated glucan resulted in some reduction of larval counts in mice infected with the nematode *Toxocara canis*, and also that anthelmintics co-administered with liposomized glucan were much more effective than drug alone (Velebný *et al.*, 1997).

Invasion of the host by the parasites frequently leads to tissue damage and its extent may be assessed by monitoring of enzyme levels abundant in the insulted organs, which are released into the blood (White *et al.*, 1982). Two enzymes, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) seem to be good markers of pathological changes in the liver parenchyma (George & Chandrakasan, 2000).

In the present study we evaluated the effect of glucan, liposomized glucan alone or in combination with vitamin C and empty liposomes in mice infected with *Mesocestoides corti* tetrathyridia originally isolated and described by Specht & Voge (1965) and renamed as *M. vogae* by Etges (1991). Larval counts in the liver and peritoneal cavity, extent of liver fibrosis, level of cholesterol and activity of hepatocyte enzymes ALT and AST in serum were examined.

Materials and methods

**Parasite and host**

Tetrathyridia of *Mesocestoides corti* were obtained from the body cavity of male mice (ICR strain) and maintained in Hanks balanced salt solution (HBSS, Sigma, USA) until infection. In the experiments male mice of the same strain, aged 6–7 weeks, were orally inoculated with 55–60 tetrathyridia in 0.5 ml saline.

**Drugs and liposomes**

β-glucan (carboxymethylated β-1,3-D-glucan; Mevak, Slovak Republic) was dissolved in saline (1 mg ml⁻¹) and intramuscularly administered (single dose contained 5 mg per kg body weight). Vitamin C was dissolved in water (2 mg ml⁻¹) and perorally administered at 8 mg kg⁻¹.

Glucan was entrapped into liposomes according to the method of Bangham *et al.* (1965). Briefly, chloroform-methanol (2:1, v/v) solution of the mixture consisting of 0.056 mmol Phospholipon 100H (Natterman Phospholipid; Koln, Germany), 0.016 mmol cholesterol and 0.008 mmol dicetylphosphosphate (Serva, Heidelberg, Germany) was dried under the reduced pressure forming the lipid film. This film was hydrated by 40 ml of 0.1% glucan solution (in saline), yielding a 1 mg ml⁻¹ preparation, which was administered subcutaneously at 5 mg glucan per kg body weight.

Empty liposomes were prepared by the same method and contained Phospholipon 100H and cholesterol at the concentration 1.1 and 0.15 mg ml⁻¹, respectively. They were administered subcutaneously at 5.5 mg Phospholipon 100H and 0.8 mg cholesterol per kg body weight.

**Experimental design**

Infected mice were divided into five groups comprising 40 individuals each. Mice without treatment served as...
control (group 1). The remaining groups of mice were treated with the following preparations: glucan (group 2), liposomized glucan (group 3), liposomized glucan co-administered with vitamin C (group 4) and empty liposomes (group 5). Preparations were administered every third day from day 7 to day 31 p.i., for a total of nine doses.

Sera from five mice in each group were prepared from blood samples collected before infection and on days 11, 15, 21, 28, 32, 50 and 65 post-infection (p.i.) and were used for the determination of enzyme activity (ALT and AST) and cholesterol levels. Hydroxyproline levels were determined in the liver of five mice sacrificed on the same days p.i. (5 mice each day of examination). This schedule allowed us to monitor changes both during the course of administration and up to a month after termination of therapy. Larvicidal effects of the preparations were evaluated after isolation of tetrathyridia from the liver and peritoneal cavity on day 65 p.i. as described previously (Hřčková & Velebný, 1995). The experiment was repeated twice.

**Results**

**Larval counts in the liver and peritoneal cavity**

The numbers of larvae recovered from the liver (1 g) and peritoneal cavity of mice in all five groups on day 65 p.i. are shown in fig. 1. After nine doses of either glucan formulation, a significant reduction of larvae \((P < 0.01)\) relative to controls was found in both tissues. In the liver the efficacy of glucan formulations was nearly the same, whereas in the peritoneal cavity, treatment with liposomized glucan in combination with vitamin C resulted in lower larval counts than treatment with glucan only. Interestingly, the administration of empty liposomes resulted in more larvae occurring in peritoneal cavity \((P < 0.05)\).

**Collagen content in the liver**

The process of fibrosis in the liver was followed during and after treatment up to 65 days p.i. The collagen content, measured by means of hydroxyproline concentration, is shown in table 1. In the infected untreated group it increased gradually up to day 50 p.i. In the group treated with glucan and liposomized glucan, the hydroxyproline concentration was significantly higher \((P < 0.001)\) on most days than in the control group. The administration of empty liposomes had no effect on the hydroxyproline content. The most pronounced increase of total collagen in the liver was recorded in the group treated with liposomized glucan in combination with vitamin C. This group also showed the most intense fibrosis and the highest hydroxyproline concentration \((P < 0.001)\) relative to the glucan-treated group. The most prominent increase of hydroxyproline content in this group was observed between days 50 and 65 p.i.

**Serum activities of AST**

Aspartate aminotransferase is present in the cytoplasm and mitochondria of cells, therefore it is considered a suitable marker to monitor cell damage or proliferation. Parasitization by *M. corti* larvae in the liver resulted in the...
The administration of empty liposomes resulted in an elevation of AST activities in control mice from these groups dropped significantly within the first month p.i. Maximum AST activities were recorded. The co-administration of vitamin C with this liposomized glucan resulted in even higher serum levels recorded. The administration of glucan increased ALT levels in serum of mice from these groups, while treatment with glucan had no significant impact on this parameter, liposomal formulations of glucan resulted in a significant increase. While treatment with glucan had no significant impact on this parameter, liposomal formulations of glucan resulted in a significant increase (P < 0.001). The co-administration of vitamin C with this liposomized glucan administration with vitamin C. The administration of empty liposomes resulted in an elevation of activity up to day 42 p.i. (P < 0.001). In all treated groups the activity of this enzyme reached maximal values between days 28 and 32 p.i., then declined, indicating a progressive repARATION of cell membranes in the chronic stage of infection.

**Cholesterol levels in serum**

Parenchymal cells are involved in the metabolism of lipids and this activity is limited after tissue injury. In contrast to the increasing enzyme activities in control mice with ongoing infection, cholesterol levels declined in this group (table 4). The most pronounced elevation of cholesterol was found in mice given empty liposomes (P < 0.001). While treatment with glucan had no significant impact on this parameter, liposomal formulations of glucan resulted in a significant increase (P < 0.001) in serum cholesterol levels. Peak levels in all groups were observed between days 28 and 32 p.i., concurrent with termination of therapy. After this, levels of cholesterol gradually decreased in all groups.

**Discussion**

Fibrosis and formation of collagenous capsules around parasites in the liver is one of the most severe consequences of infection by *M. corti*. This process also reduces the amount of drug to which larvae are exposed (Hříková et al., 1997). We demonstrated that soluble glucan, administered consecutively in low

was markedly elevated on day 14 p.i., but IFN-γ production by T-cells was down-regulated during infection (Jenkins et al., 1990). IFN-γ is a very strong immunomodulatory cytokine and was found to decrease collagen synthesis in cultured myofibroblasts (Mallat et al., 1995). However, in M. corti infections, detailed studies on the role of cytokines in liver fibrosis are lacking.

In the present study, the progression of fibrosis was investigated by measuring the hydroxyproline content in the liver during the administration of nine doses of the glucan and liposomized glucan preparations alone or co-administered with vitamin C, and empty liposomes up to day 65 p.i. The collagen content in the liver increased gradually in all groups. On histological examination, fibrosis was more intense with progressing infection. In E. multilocularis infection Guerret et al. (1998) found that the concentration of lysyl oxidase, an enzyme that correlates with cross-linking activity of mature collagen (type I), increased with progressing fibrosis and growth of parasite cysts. Histologically, a similar increase in granulomatous response, collagen deposition and fibrosis was observed after the administration of multiple doses of lentinant to M. corti infected mice (White et al., 1988).

In the latter and the present studies many larvae were damaged or appeared dead. We recorded only minor differences in collagen content between glucan alone versus liposomized glucan-treated groups. We found the most intense fibrosis after the administration of liposomized glucan in combination with vitamin C. The role of vitamin C in the organism is well defined, and its presence for the synthesis of collagen is essential (Murad et al., 1981). Thus we hypothesize that the addition of vitamin C contributed to the increased collagenesis in addition to the stimulation of this process by glucan.

The stimulation of liver fibrosis is an extremely complex event in which hepatic stellate cells (HSC) are responsible for the synthesis of collagenous and non-collagenous extracellular matrix components and other biologically active molecules (Friedman, 1993). In vivo, activated HSC are present in chronically diseased liver, especially during liver fibrosis. In acute injuries, the factor responsible for transformation of perisinusoidal cells to HSC is hepatocyte necrosis followed by activation of Kupffer cells (Burt, 1993). There are several factors that induce this transformation including growth factors, cytokines and chemokines. These are products of oxidative stress released mainly from Kupffer cells (Tsukamoto, 1999). Thus, we hypothesize that in glucan-enhanced fibrosis, recruited macrophages (including Kupffer cells) probably produced a stronger activating signal for HSC. In the case of treatment with liposomized formulations of glucan, TNF-α was probably not the main factor responsible for activation of HSC. This is based on the findings of Tonks et al. (2001), who showed that dipalmityl phosphatidylcholine (DPPC), the major component of liposomes used in the present study, can significantly inhibit the release of TNF-α from monocytes.

In agreement with this hypothesis was our finding that empty liposomes did not modify collagen content except for on the last day of the experiment.

Damage to hepatic stellate cells causes release of their intracellular constituents into the blood. Sensitive indicators of such damage include plasma levels of the enzymes AST and ALT (Zilva & Pannall, 1984). Following M. corti infection, the activity of both enzymes gradually increased, peaking between days 32 and 42 p.i., then declining over the next month. Levels of ALT, which is restricted to the cytoplasm, were lower in comparison to AST, which is localized in the mitochondria and cytoplasm (Zilva & Pannall, 1984). The same pattern in both enzyme activities during M. corti infection was observed by White et al. (1988) and Velebný & Hřcůvka (1995). Glucan administration did not result in a marked elevation of both enzymes activities. Liposomized glucan and empty liposomes significantly elevated ALT levels, most prominently when co-administered with vitamin C. This finding correlates with increased collagen deposition. Under conditions in which cell membrane damage occurs, more ALT than AST leaks into the blood (Zilva & Pannall, 1984). It is possible that redistribution of liposomal phospholipids from Kupffer cells to hepatocytes influenced the permeability of their membranes (Scherpbof et al., 1983), thus some leakage of ALT might occur. On the other hand, AST activities decreased significantly from day 32 p.i. in groups with liposomal formulations. As this enzyme activity is indicative of whole cell damage (Zilva & Pannall, 1984), the administration of glucan in a liposomal carrier seems to stimulate regeneration of liver tissue. Liver regeneration is a fundamental response to injury of hepatic tissue, due to the capacity of hepatocytes to proliferate rapidly. It was postulated by Takeishi et al. (1999) that in this process, Kupffer cells play a key role by stimulating the expression of hepatocyte growth factor (HGF) in HSC. HGF is the most potent mitogen for hepatocytes and its specific binding to liver collagens was described by Schuppan et al. (1998). The more intense collagenesis and repair of liver parenchyma in liposomized glucan- and vitamin C-treated mice could be a consequence of HGF activity.

Hepatocytes play an important role in the metabolism of exogenous and endogenous lipids, and liver injury often reduces metabolic and biosynthetic activities of these cells. Indeed, all chronic liver diseases lead to a depression of total serum cholesterol levels (George & Chandrakasan, 2000). Therefore we monitored serum cholesterol levels during and after therapy. It is important to note that serum cholesterol levels reflect a dynamic ratio between cholesterol excretion from other cells, its uptake by the parenchymal cells and synthesis (Musil, 1990). Higher levels of cholesterol in the control group during the acute phase of infection by M. corti might reflect liver damage leading to the release of more cholesterol into the blood. As liver repair began on days 28–32 p.i. (Specht & Widmer, 1972; personal observations), cholesterol levels declined but did not reach the physiological levels, probably because fibrous tissues replaced a substantial portion of the liver parenchyma. Decreased cholesterol synthesis in hepatocytes from a cirrhotic liver was described by Zimmermann et al. (1992).

Glucan administration did not modify significantly cholesterol levels, ALT and AST activities, although the collagen content increased significantly. We might conclude that although glucan treatment activates the antiviral capacity of phagocytic cells, one of which is increased fibrosis, it did not stimulate regenerative processes in livers infected with larval stages of M. corti.
The administration of a liposomal formulation of glucan or empty liposomes lead to a significant elevation of serum cholesterol levels up to days 28–32 p.i. Following that, in the control group, cholesterol values decreased. This might suggest that the synthetic capacity of liver cells for cholesterol was improved due to the utilization of exogenous lipids correlating with lowered serum AST activities, a marker for hepatocyte necrosis. Later, when re-utilization of liposomal lipids was probably completed, cholesterol levels in the serum levelled down in all groups, but remained significantly higher than in untreated controls.

In summary, the present study has shown that intense fibrosis in the liver of mice treated with liposomized glucan and vitamin C did not result in extensive parenchymal cell injury but, rather, in a higher efficacy of treatment. Moreover, liposomal lipids may be utilized by liver cells in the process of regeneration. Targeting of liposomized immunomodulator glucan directly to the phagocytic cells may overcome problems associated with their suppressed accessory and effector functions.
